PURPOSE. The mutation R345W in EFEMP1 (fibulin-3) causes macular degeneration. This study sought to determine whether proteoglycan content and diffusion across Bruch’s membrane are altered in Efemp1R345W mice carrying this mutation or in Efemp1+/− mice.

METHODS. Proteoglycans in mouse Bruch’s membranes were stained with Cupromeronic Blue (CB). Heparan sulfated proteoglycan (HSPG) and chondroitin/dermatan sulfate proteoglycan (C/DSPG) distributions were visualized following treatments with chondroitinase ABC (C-ABC) or nitrous acid. Total sulfated glycosaminoglycans (sGAGs) in Bruch’s membrane/choroid (BrM/Ch) were measured with dimethylmethylene blue (DMMB). Matrix metalloprotease (MMP)-2, MMP-9, and tissue inhibitor of metalloproteinase (TIMP)-3 were examined by immunofluorescence and quantified using Image J. Molecules with different Stokes radius (Rs) were allowed simultaneously to diffuse through mouse BrM/Ch mounted in a modified Ussing chamber. Samples were quantified using gel exclusion chromatography.

RESULTS. HSPGs and C/DSPGs were markedly increased in Efemp1R345W Bruch’s membrane, and MMP-2 and MMP-9 were decreased, but TIMP-3 was increased. Diffusion across Efemp1R345W Bruch’s membrane was impaired. In contrast, the proteoglycan amount in Efemp1+/− Bruch’s membrane was not significantly different, but the size of proteoglycans was much larger. MMP-2, MMP-3, and TIMP-3 levels were similar to that of Efemp1+/− mice, but they were localized diffusely in retinal pigment epithelium (RPE) cells instead of Bruch’s membrane. Diffusion across Efemp1+/− Bruch’s membrane was enhanced.

CONCLUSIONS. Mutant fibulin-3 causes proteoglycan accumulation, reduction of MMP-2 and MMP-9, but increase of TIMP-3, and impairs diffusion across Bruch’s membrane. Fibulin-3 ablation results in altered sizes of proteoglycans, altered distributions of MMP-2, MMP-9, and TIMP-3, and enhances diffusion across Bruch’s membrane.

Keywords: age-related macular degeneration, Malattia Leventinese, EFEMP1 (fibulin-3), proteoglycans, diffusion
In contrast, BLamD is not observed in mice recapitulate the important histopathology of ML/DHRD. Fibulin-1 is a co-factor for proteoglycanase ADAMTS-1 (a) activities of MMPs and TIMPs. The mutation in fibulin-3 may alter proteoglycan content, affect diffusion across Bruch's membrane, and lead to retention of materials and sub-RPE deposit formation.

In Efemp1^+/-/ki mice that carry the R345W mutation, basement membrane-like materials accumulate between the plasma and basement membranes of the RPE to form BLamDs. Lipid-rich debris is retained within continuous sheets of BLamDs. There is also an accumulation of heterogeneous materials in a thickened Bruch's membrane. It is possible that fibulin-3 functions to regulate the turnover of proteoglycans in Bruch's membrane through modifying the activities of MMPs and TIMPs. The mutation in fibulin-3 may alter proteoglycan content, affect diffusion across Bruch's membrane, and lead to retention of materials and sub-RPE deposit formation.

The cationic dye Cupromeronic Blue (CB) binds glycosaminoglycan side chains of sulfated proteoglycans. Different types of proteoglycans bound to CB can be visualized under electron microscopy as filaments with different sizes and electron density. CB staining coupled with treatments that can be used as tools for studying the role of fibulin-3 in Bruch's membrane and the underlying mechanism by which mutant fibulin-3 causes sub-RPE deposit formation.

Methods

Mice

Efemp1^+/-/ki and Efemp1^-/- mice were generated previously. Mice were handled in accordance with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research, using protocols approved by the Institutional Animal Care and Use Committee of the University of Arizona or Mayo Clinic. Animals were housed under standard conditions and maintained on a 12-hour light/dark cycle with free access to food and water.

Proteoglycan Distribution in Bruch's Membrane

Eyes from 9-month-old wild-type (Efemp1^+/-/ki), Efemp1^+//-, and Efemp1^-/- mice were fixed at 4°C in 1% formaldehyde, 2% glutaraldehyde in 0.1 M phosphate buffer, pH 7.4. Chorioretinal tissues were dissected from fixed eyes, cut into strips, and divided into four groups for enzymatic or nitrous acid treatment: (group 1) control group without enzyme or nitrous acid treatment; (group 2) C-ABC (Sigma-Aldrich Corp., St. Louis, MO, USA) treatment; (group 3) nitrous acid (Sigma-Aldrich Corp.) treatment; and (group 4) combinational treatment with both C-ABC and nitrous acid. For C-ABC treatment, tissue strips were incubated with 1 unit/mL C-ABC in 0.25 M Tris buffer containing 0.05% BSA, 5 mM benzamidine-HCl, and 0.1 M 6-amino-capric acid, pH 8.0, at 37°C for 24 hours. For nitrous acid treatment, tissue strips were incubated in a nitrous acid solution containing 5% sodium nitrite, 35% acetic acid, 5 mM benzamidine-HCl, and 0.1 M 6-amino-capric acid for 90 minutes at room temperature. Each group of tissue strips was then stained with 0.05% CB (Sigma-Aldrich Corp.) in 25 mM sodium acetate, 0.2 M MgCl2 and 2.5% glutaraldehyde, pH 5.7 overnight as described. After staining, tissue strips were processed for transmission electron microscopy. Thin sections were cut with a Reichert Ultracut microtome, stained with uranyl acetate and lead citrate, and imaged with a Philips CM-12 electron microscope equipped with an AMT CCD camera (Advanced Microscopy Techniques Corp., Danvers, MA, USA).

CB-stained proteoglycan filaments were quantified by counting the filaments from different view fields at the same magnification. Specimens from three individual mice for each genotype were included in the filament quantification. Three sections from each specimen were used, and 10 different fields from each section were counted. The numbers of filaments from Efemp1^+/-/ki or Efemp1^-/- mice were compared with those in Efemp1^-/- mice using a Student’s t-test. Proteoglycan filament lengths were measured using the Adobe Photoshop ruler tool. Ten different filaments per field for each category (HSPG or C/DSPG) were measured. Due to their small size, filament lengths were measured to the nearest 5 nm.

sGAG Quantification Assay

After mice were killed with CO2 asphyxiation, eyes from 9-month-old Efemp1^+/-/ki, Efemp1^+/-/ki, and Efemp1^-/- mice were enucleated, and the lens and anterior segments were removed. The retina was detached using forceps, the eyecup filled with PBS buffer, and the RPE was removed using a fine camel’s hair brush. The BrM/Ch was detached from the sclera, weighed, and minced. Five sets of BrM/Ch samples from five mice per genotype (Efemp1^+/-/ki, Efemp1^+/-/ki, or Efemp1^-/-) were analyzed. Samples were digested with 300 µg papain (Sigma-Aldrich Corp.) in 100 mM sodium phosphate buffer (pH 6.8) containing 1 mM EDTA and 2 mM dithiothreitol at 60°C for 2 hours. Samples were diluted with 10 mM iodoacetate and
50 mM Tris/HCl (pH 8.0). The sGAG content in papain-digested samples was measured by colorimetric assay with DMMB using an assay kit (Amresco, Cambridge, MA, USA) according to the manufacturer’s instructions. sGAG measurements from Efemp1ki/ki or Efemp1−/− mice were compared with those in Efemp1+/+ mice using a Student’s t test.

**Immunofluorescence**

Eyes from 9-month-old Efemp1+/+, Efemp1ki/ki, and Efemp1−/− mice were fixed in 4% paraformaldehyde. Immunofluorescence staining of 10-μm frozen sections of mouse eyes was performed as previously described using a rabbit polyclonal antibody against MMP-2 (Abcam, Cambridge, MA, USA), MMP-9 (Abcam), TIMP-3 (Abcam), or fibulin-3. A goat anti-rabbit IgG (Jackson, NY, USA) was used as a secondary antibody (Invitrogen, Carlsbad, CA, USA). Cell nuclei were stained with 4′,6-diamidino-2-phenylindole (DAPI). Sections were examined and photographed using a Nikon E600 microscope (Melville, NY, USA) equipped with a CCD camera.

Quantification of immunofluorescence was performed using Image J software (National Institutes of Health, Bethesda, MD, USA). Sections from three mice (n = 3) per genotype (Efemp1+/+, Efemp1ki/ki, or Efemp1−/−) were used. Three images taken from three randomly selected areas in each stained section were measured. In each image, the outline of the RPE layer and Bruch’s membrane was drawn, and the area, mean fluorescence, and background readings were measured. The total fluorescence was calculated as integrated density subtracting (area of selected sections multiplying mean fluorescence of background readings). Fluorescence from Efemp1ki/ki or Efemp1−/− mice was compared with that in Efemp1+/+ mice using a Student’s t test.

**Diffusion Assay**

The BrM/Ch prepared from 9- or 18-month-old Efemp1+/+, Efemp1ki/ki, and Efemp1−/− mice was mounted between two pieces of X-ray film, which had corresponding 1.0-mm diameter drilled holes and were coated with a thin layer of silicon grease. Diffusion of molecules through mouse BrM/Ch was studied using a dual Ussing chamber model U2500 (Warner Instruments, Hamden, CT, USA). The BrM/Ch/X-ray film “sandwich” was mounted, separating the two chambers with only the 1.0-mm diameter circle of BrM/Ch allowing communication between them. Four molecules with different Rs were selected for their ability to separate cleanly by gel exclusion chromatography, cytosine (molecular weight [MW] = 110.1, Rg < 1.0 nm; Sigma-Aldrich Corp.), RNase A (MW = 13,700, Rg = 1.72 nm; Teknova, Hollister, CA, USA), human serum albumin (MW = 66,382, Rg = 3.55 nm; EMD Chemicals, Gibbstown, NJ, USA), and horse spleen ferritin (MW = 450,000, Rg = 6.15 nm; EMD Chemicals). A mixture of these molecules dissolved in PBS with 1 mM MgCl2 and 0.1 mM CaCl2 (PBS-CM) was added to the reservoir on the BrM side of the tissue with only PBS-CM on the Ch side.

**Flux and Permeability Coefficients**

Flux and permeability coefficients were calculated as previously described. Molecules were quantified after 48 hours using gel exclusion chromatography with a 1.6 × 60 cm Hi-Prep Sephadryl S-500HR (Amersham Biosciences, Piscataway, NJ, USA) column equilibrated with PBS-CM. The column was developed at a linear flow rate of 15 mL cm⁻¹ h⁻¹ using an AKTA prime chromatography system controlled by PrimeView software (GE Healthcare Life Sciences, Pittsburgh, PA, USA). Peaks were detected by their absorbance at 280 nm, and peak areas were determined by integration using PrimeView software. Solute concentrations were quantified by linear regression analysis using peak areas derived from known quantities of each test molecule. Flux (J) was calculated using the equation J = (C/C1 - t) where C = accumulated molar concentration, A = the area (cm²) of the exposed tissue (0.000785 cm²), and t = 48 hours. Permeability coefficients (P) were calculated using Fick’s first law: P = (J/L)/AC where L = the thickness of the BrM/Ch preparation and AC describes the difference in moles of molecules between the two compartments of the Ussing chamber.

**RESULTS**

Rod-like filaments representing sulfated proteoglycans were observed at high magnifications under electron microscopy in Bruch’s membrane of 9-month-old Efemp1+/+, Efemp1ki/ki, and Efemp1−/− mice after CB staining (Fig. 1). The size and number of filaments were different in mice with different Efemp1 genotypes (Fig. 1). In Efemp1+/+ Bruch’s membrane, filaments with an average length of 50 nm were observed in the collagenous/elastic fibrous layers, and filaments with an average length of 40 nm were observed in the basement membranes of the RPE and endothelium of choriocapillaris (Figs. 1A, 1a1, 1a2; Table 1). Smaller sizes of filaments may represent the same type of filaments cut shorter during sectioning or only partially visible in any given microscopic viewing field. Filaments in the fibrous layers were eliminated by C-ABC treatment (Fig. 2), indicating that they were C/DSPGs. Filaments in the basement membranes were removed by nitric acid treatment (Fig. 3), indicating that those filaments were HSPGs. Combined treatment of both C-ABC and nitric acid eliminated all the filaments from Bruch’s membrane (Fig. 4). This indicates that all the filaments observed were either HSPGs or C/DSPGs.

**Proteoglycan Accumulation in Bruch’s Membrane of Efemp1ki/ki Mice**

Markedly increased filaments were observed in Bruch’s membrane of Efemp1ki/ki mice (Figs. 1B, 1b1, 1b2). By counting the filaments from different view fields at the same magnification, we determined that there were on average three times as many filaments in Efemp1ki/ki Bruch’s membrane as in Efemp1+/+ Bruch’s membrane (Table 2).

After C-ABC treatment, filaments with an average length of 40 nm (Table 1) representing HSPGs remained in the basement membranes of the RPE and endothelium of choriocapillaris in Efemp1ki/ki mice (Fig. 2). There were 2.35 times as many filaments in Efemp1ki/ki basement membranes as those in Efemp1+/+ mice (Table 2). After nitrous acid treatment, filaments with an average length of 50 nm (Table 1) representing C/DSPGs remained in the fibrous layers of Efemp1ki/ki Bruch’s membrane (Fig. 3). There were 4.15 times as many filaments in Efemp1ki/ki fibrous layers as those in Efemp1+/+ fibrous layers (Table 2). Combined treatment of C-ABC and nitric acid eliminated all the filaments from Efemp1ki/ki Bruch’s membrane (Fig. 4), indicating that all the filaments observed were either HSPGs or C/DSPGs.

Biochemical analysis by DMMB colorimetric assays revealed that total sGAG content in 9-month-old Efemp1ki/ki BrM/Ch was significantly higher than that of Efemp1+/+ mice (Fig. 5). The average amount of sGAGs in Efemp1ki/ki BrM/Ch was 15.89 μg/mg wet tissue weight, comparing to 10.15 μg/mg in Efemp1+/+ mice.
Different Sizes of Proteoglycans in Bruch’s Membrane of Efemp1<sup>-/-</sup> Mice

In Efemp1<sup>-/-</sup> mice, there were slightly more filaments observed in Bruch’s membrane than in Efemp1<sup>+/+</sup> mice, but the difference was not statistically significant (Table 2). However, the size of filaments in Efemp1<sup>-/-</sup> Bruch’s membrane was strikingly larger (Figs. 1C, 1c1, 1c2). After C-ABC treatment, filaments with an average length of 120 nm (Table 1) representing HSPGs were observed in Efemp1<sup>-/-</sup> basement membranes of the RPE and endothelium of choriocapillaris.

treated with nitrous acid and stained by CB. Note that filaments representing HSPGs in the basement membranes of the RPE and the endothelium of choriocapillaris were preserved. BI, basal infolding; BM, basement membrane; EN, endothelium. Scale bar: 500 nm.

After nitrous acid treatment, filaments with an average length of 105 nm (Table 1) representing C/DSPGs were observed in the fibrous layers of Efemp1+/- Bruch’s membrane (Fig. 3). Despite the different sizes, combined treatment of C-ABC and nitrous acid eliminated all the filaments from Bruch’s membrane, but that filaments (arrows) representing HSPGs in the fibrous layers of Bruch’s membrane were slightly lower than that in Efemp1+/+ mice, but the difference was not statistically significant (Fig. 6B).

Different Diffusion Rates Across Mouse Bruch’s Membrane of Efemp1+/+, Efemp1ki/ki, and Efemp1-/- Mice

We previously established a system using a modified Ussing chamber coupled with quantitative gel exclusion chromatography to study the diffusion of multiple molecules with different Rs through small samples (<2 mm²) of Bruch’s membrane.41 Here we used this system to measure differences in the diffusion of four molecules through Bruch’s membrane of 9- and 18-month-old Efemp1+/+, Efemp1ki/ki, and Efemp1-/- mice in the BrM to Ch direction. We established a concentration gradient of all four molecules across BrM/Ch and applied Fick’s first law to calculate the flux and permeability coefficient of each molecule as described previously.41 The flux of each molecule remained constant, and the concentration gradient was not significantly influenced by the diffusion of molecules throughout the time course of each experiment. Flux and permeability coefficient decreased with increasing Rs (Fig. 7).

For Efemp1+/+ tissue (n = 5 mice per age), cytosine had a flux of $5.33 \times 10^4$ (9 months) and $2.99 \times 10^4$ mmol cm⁻² h⁻¹ (18 months), and a permeability coefficient of 0.94 (9 months)
and 0.47 cm⁻² h⁻¹ (18 months). Ferritin had a flux of 1.32 (9 months) and 0.86 nmol cm⁻² h⁻¹ (18 months), and a permeability coefficient of 9.25 × 10⁻⁵ (9 months) and 2.38 × 10⁻⁵ cm⁻² h⁻¹ (18 months). Flux and permeability coefficient of each molecule were higher for 9-month-old than 18-month-old tissue (Fig. 7).

We found both flux and permeability coefficients of each molecule were significantly (P < 0.05) decreased for BrM/Ch samples from Efemp1ki/ki mice (n = 5 for 9 months old, and n = 6 for 18 months old) (Fig. 7). Cytosine had a flux of 8.54 (9 months) and 6.71 nmol cm⁻² h⁻¹ (18 months), and a permeability coefficient of 6.92 × 10⁻⁴ (9 months) and 2.24 × 10⁻⁴ cm⁻² h⁻¹ (18 months). Ferritin had a flux of 4.80 × 10⁻² (9 months) and 1.47 × 10⁻² nmol cm⁻² h⁻¹ (18 months), and a permeability coefficient of 1.01 × 10⁻⁶ (9 months) and 3.13 × 10⁻⁷ cm⁻² h⁻¹ (18 months). This indicates that diffusion across Bruch’s membrane of Efemp1ki/ki mice was markedly decreased, with ferritin virtually impermeable at both 9 and 18 months of ages.

In contrast to Efemp1ki/ki mice, we found increased flux and permeability coefficient of each molecule for BrM/Ch samples from Efemp1+/+ mice (n = 6 for 9 months old, and n = 8 for 18 months old) (Fig. 7). Cytosine had a flux of 1.13 × 10⁻² (9 months) and 4.79 × 10⁻³ nmol cm⁻² h⁻¹ (18 months), and a permeability coefficient of 5.30 (9 months) and 2.93 cm⁻² h⁻¹ (18 months). Ferritin had a flux of 3.98 nmol (9 months) and 2.19 nmol cm⁻² h⁻¹ (18 months), and a permeability coefficient of 5.56 × 10⁻⁴ (9 months) and 1.12 × 10⁻⁴ cm⁻² h⁻¹ (18 months). This indicates that diffusion across Bruch’s membrane of Efemp1+/+ mice was increased at both 9 and 18 months of ages. The permeability coefficient was similar for albumin and ferritin for BrM/Ch samples from either Efemp1+/+ or Efemp1+/− mice (Fig. 7B), suggesting that the ferritin is near the physical size exclusion limit of Bruch’s membrane for these mice.

**DISCUSSION**

The R345W mutation in fibulin-3 causes sub-RPE deposit formation both in human and mouse, but the pathogenic mechanism behind this remains unknown. In this study, we have found that Efemp1ki/ki mice carrying this mutation have markedly increased sulfated proteoglycans in their Bruch’s membrane, although the type and size of proteoglycans are similar to those found in the wild-type mice. Both HSPGs and C/DSPGs are substantially increased. In Efemp1+/− mice, which do not express fibulin-3, we have found that the sizes of HSPGs and C/DSPGs are significantly larger than those observed in wild-type mice, but their amount is not significantly different. These results indicate that fibulin-3 regulates the level and type of proteoglycans in Bruch’s membrane.

The accumulated proteoglycans in Efemp1ki/ki mice can be due to either over-synthesis or deficient degradation. Our data suggest that deficient degradation may be a more important factor. MMP-2 and MMP-9, two ECM enzymes with known proteoglycanase activities, are significantly decreased in Efemp1ki/ki Bruch’s membrane, but TIMP-3, an inhibitor of MMPs, was not significantly decreased.

**FIGURE 5.** Total amount of sGAG of BrM/Ch samples from 9-month-old mice. Error bars indicate the mean ± SD. n = 5 mice per genotype. *P < 0.05 comparing to the value of Efemp1+/+ mice. +/+: Efemp1+/+; ki/ki, Efemp1ki/ki; −/−, Efemp1+/−.
a broad range of proteoglycanases, is significantly increased. Without fibulin-3 in \textit{Efemp}\textsuperscript{1/+}, mice, MMP-2, MMP-9, and TIMP-3 are diffusely localized in RPE cells instead of Bruch’s membrane. Bruch’s membrane. This accumulation could provide a high level of localized inhibitory activity on proteoglycanase(s) and cause proteoglycan accumulation in Bruch’s membrane. Fibulin-3 is overexpressed by senescent cells in aging tissues.\textsuperscript{43,44} It accumulates in Bruch’s membrane of both MJD/HRD and AMD donor eyes.\textsuperscript{25} There is no fibulin-3 mutation found in AMD patients.\textsuperscript{33,34} This supports the idea that elevated fibulin-3 activity from fibulin-3 accumulation due to mutation or aging causes pathologic changes associated with sub-RPE deposits.

Studies on the composition of sub-RPE deposits have found that lipoproteins, cholesterol, and products of the complement system are common components of sub-RPE deposits.\textsuperscript{45–52} This leads to an ocular “response-to-retention” hypothesis for sub-RPE deposit formation reminiscent of that for atherosclerosis,\textsuperscript{45} which proposes that lipoproteins are retained on proteoglycans in the arterial intima, become modified, and then elicit an inflammatory response leading to atherosclerotic plaque formation.\textsuperscript{45–52} We have previously found that lipid-containing particles (previously referred to as membranous debris) accumulate in linear tracks within BLMs in \textit{Efpmp}\textsuperscript{1/ki} mice.\textsuperscript{45,53} Our findings here suggest that the lipid-containing particles may be trapped by the proteoglycans accumulated in Bruch’s membrane, thus, leading to the exposure of retained lipids to the high oxidative stress environment at the RPE/Bruch’s membrane interface. Oxidative modification of lipids triggers complement activation to remove the oxidatively damaged molecules.\textsuperscript{54} The sustained supply of lipids trapped in proteoglycans can turn complement activation into chronic inflammation with the accumulation of inflammatory products to form sub-RPE deposits.

Proteoglycans affect the diffusion properties of Bruch’s membrane. Consistent with the changes in proteoglycans in \textit{Efpmp}\textsuperscript{1/ki} and \textit{Efpmp}\textsuperscript{1/ki} mice, we have found that diffusion across Bruch’s membrane is impaired in \textit{Efpmp}\textsuperscript{1/ki} mice, but enhanced in \textit{Efpmp}\textsuperscript{1/ki} mice. Both flux and permeability coefficient decreased exponentially for all four molecules with \( R \) ranging from <1.0 to 6.15 nm for \textit{Efpmp}\textsuperscript{1/ki} mice comparing to those for the wild-type mice. This suggests that the porosity of Bruch’s membrane is greatly reduced in \textit{Efpmp}\textsuperscript{1/ki} mice. The increased amount of proteoglycans in these mice may structurally obscure pores of Bruch’s membrane, or may increase the viscosity of the fibrous layers. Impaired diffusion would hinder the removal of metabolic wastes and other molecules secreted from the RPE, and accelerate the deposition of heterogeneous materials in Bruch’s membrane of \textit{Efpmp}\textsuperscript{1/ki} mice. For \textit{Efpmp}\textsuperscript{1/ki} mice, the flux and permeability coefficient across Bruch’s membrane are more in line with those of the wild-type mice, but the increase is significant. The substantially larger sizes of proteoglycans in \textit{Efpmp}\textsuperscript{1/ki} mice may structurally expand pore sizes of Bruch’s membrane resulting in enhanced diffusion as we observed.

In summary, our study has found that mutant fibulin-3 causes proteoglycan accumulation and impaired diffusion across Bruch’s membrane. Fibulin-3 may have specific proteoglycanase substrate(s). It would be worthwhile to investigate this in future studies. The impairment of diffusion across Bruch’s membrane would block nutrient and waste flow to and from the retina, contribute to the initiation and/or growth of sub-RPE deposits, and induce degeneration of the RPE and photoreceptors. The enhanced diffusion across Bruch’s membrane of \textit{Efpmp}\textsuperscript{1/ki} mice suggests that reduction or elimination of fibulin-3 could be a valuable strategy in developing treatments for macular degeneration.
