We read with great interest the recent article by Yuki et al.1 It is very thought-provoking that the authors predicted the likelihood of a future motor vehicle collision (MVC) among patients with primary open-angle glaucoma (POAG) based on multiple attributes using the penalized support vector machine (pSVM). However, several points remain to be discussed in terms of model design, data interpretation, as well as clinical application.

On one hand, the design of the model is somewhat controversial (recapitulation in Fig. 1A). The high-dimensional dataset (62 variables in the predpenSVM_basic model and 84 variables in the predSVM and predpenSVM_all models) is inclined to overfit when the sample size is small, because the cover range is not sufficient for pattern recognition on each attribute.² Elaboration of attributes’ contribution is a promising alternative to address this issue. Model simplification (excluding the less contributed attributes) will broaden dramatically the application merit and be more cost-effective. Moreover, the progress of POAG and corresponding controlling efficacy have been reported to exhibit great heterogeneity.³ Thus, potential indicators regarding intraocular pressure, visual field, and drug intake should be included. Given that best-corrected visual acuity has a significant effect on the likelihood of MVC, other variables of visual function, including refractive conditions, stereoscopic vision, contrast sensitivity, and color vision, can improve the model performance as well.⁴,⁵

On the other hand, the model validation and its clinical merit should be interpreted cautiously (recapitulation in Fig. 1B). First concern lies in the consistency of predicted results among patients at the three involved centers. Differences should be evaluated carefully to investigate whether this predictive model could be extended to patients at other...
centers or areas. Second, the age range (with a span of above 40 years) should be stratified before modeling due to the distinct behavioral pattern and life-styles among different generations. Third, the predicted outcome is equivocal; it is unclear whether intervention should be conducted based on a probability. Alternatively, the classification outcome could provide direct and reliable guidelines. Classifiers also could be customized to fit in various real-world situations: loose thresholds for better sensitivity in wide-range primary screening and more rigorous thresholds when making vital decision. Fourth, the predictive power varies within different time frames: it is easier to achieve strong predictive performance within the first year than within 3 years. It also is a dilemma for decision-making when facing a likely incident within a 3-year period: when will the incident happen within this span of 3 years? Should all these high-risk patients be disqualified? Therefore, a shorter-period prediction will be more practical and cost-efficient.

Machine learning for prediction promises to transform health care. However, in the “hype cycle” of emerging technologies, machine learning currently rides atop the “peak of inflated expectations”. Therefore, the capabilities and limitations of this technology should be validated and acknowledged more cautiously. Although we are conservative about the effect of the model, we appreciate the remarkable contribution made by Yuki and hope our suggestions on the design, verification and interpretation will help this work move toward real-world application.

Acknowledgments

Erping Long wrote and revised the manuscript; Peixing Wan and Yehong Zhuo revised and approved the manuscript; and Yehong Zhuo is the manuscript’s guarantor. The authors affirm that this is an honest, accurate, and transparent study; that no important aspects of this study have been omitted; and that any discrepancies from the study as planned have been explained.
