Keywords: intraocular pressure, trabecular meshwork, cytoskeleton

Purpose: To evaluate the safety, tolerability, and intraocular pressure (IOP)-lowering effect of Latrunculin-B (Lat-B), a marine macrolide that disrupts the actin cytoskeleton, in patients with ocular hypertension (OHT) or early primary open-angle glaucoma (POAG).

Methods: In this Phase I, multicenter, double-masked, randomized, placebo-controlled, ascending-dose study, subjects with bilateral OHT or early POAG (>22 mm Hg) received one of four concentrations of INS115644 (Lat-B ophthalmic solutions, 0.005%, 0.01%, 0.02%, or 0.05%) in one eye over 3 days (5 single-dose instillations, separated by 12 hours). One eye was randomly assigned to active drug, the other to placebo. IOP was measured prior to treatment initiation (day 0) and on days 1 and 3.

Results: Baseline IOPs were 22.9 ± 2.4 mm Hg and 23.5 ± 3.1 mm Hg in the 0.02% and 0.05% dose groups, respectively. At 4 hours post instillation of the first dose, 0.02% INS115644 reduced IOP from baseline (mean ± SE) by 3.8 ± 0.7 mm Hg (P = 0.002) and 0.05% by 3.9 ± 1.0 mm Hg (P = 0.004). A maximum IOP decrease of 24% was noted at 4 hours after the fifth instillation of 0.02%. Adjusting for diurnal baseline and IOP in the contralateral, placebo-treated eye, the maximal 12-hour hypotensive effect was 4.0 ± 0.5 mm Hg (adjusted mean ± SE), a 17% decrease, following the fifth instillation of 0.02% (day 3). Adverse events were few and consisted mainly of mild redness, irritation, and a transient, clinically insignificant increase (<2.5%) in central corneal thickness.

Conclusions: In OHT or POAG patients, twice daily Lat-B significantly lowered IOP compared with contralateral, placebo-treated eyes, with few and mild ocular adverse events.

Translational Relevance: Lat-B may be a potential therapeutic agent for glaucoma.

Introduction

Glaucoma is the leading cause of irreversible blindness worldwide.1 Nearly 70 million people worldwide, 1% to 4% of the population older than 45 years of age, might be affected.2 Many have the disease without knowing it. As the population ages and life expectancy increases, estimates indicate an increase in the number of persons with POAG in the United States, from 2.71 million in 2011 to 7.32 million in 2050.3 The cost of treatment was estimated to exceed $5 billion annually in 2006, in the United States alone.4

Lowering intraocular pressure (IOP) reduces the risk of disease progression5–7 and controlling IOP with topical eye drops continues to be the most common first-line therapy. Most patients will need more than one medication, from more than one class of compound, to control their IOP. The most commonly prescribed drugs act on either the ciliary process epithelia to reduce aqueous humor production (beta-adrenergic receptor antagonists) or the ciliary muscle cells to increase uveoscleral outflow...
(prostaglandin analogs that bind to and activate prostaglandin F [FP] receptors).\textsuperscript{8,9} Drugs that target the trabecular meshwork (TM) and Schlemm’s canal (SC) include cholinomimetics, which increase TM/SC outflow facility by contracting the ciliary muscle (CM), in turn distorting the TM so as to increase facility; and epinephrine, which acts directly on beta-2 adrenergic receptors in the TM/SC cells to increase TM facility (perhaps by disturbing the TM/SC cytoskeleton).\textsuperscript{10} Neither class is widely used clinically because of local (cholinomimetics) or both local and systemic (epinephrine) side effects, though they remain an alternative for patients refractory to conventional therapeutics, notably those with exfoliation syndrome/glaucoma and pigmentary glaucoma. Although cholinomimetics and epinephrine are approved and available, they are used infrequently, and there are currently no drugs commonly used clinically that directly target the TM.

In healthy eyes, the molecular pathways involved in uveoscleral and trabecular outflow and their physiologic effects work together to stimulate contraction and relaxation of the CM and TM/inner wall of Schlemm’s canal (IWSC), providing finely-tuned control of outflow.\textsuperscript{11–13} Interference with TM/IWSC cellular contractility, and cell–cell or cell–extracellular matrix adhesion, whether by inhibiting the Rho kinase or myosin light-chain kinase cascades or by disrupting actin microfilaments (whether by direct disruption or inhibition of their assembly) can result in increased outflow facility in live nonhuman primates\textsuperscript{10,14,15} and in both human and primate organ-cultured anterior segments.\textsuperscript{16–20}

Several Rho kinase inhibitor compounds are in development\textsuperscript{21–26} aiming to lower IOP by targeting trabecular outflow. Another novel agent targeting the TM is latrunculin B (Lat-B), which originates from Latrunculia (now Negombata) magnifica, a sponge from the Red Sea. Latrunculins inhibit the assembly of actin microfilaments by 1:1 molecular binding of free actin monomers in the cell cytoplasm.\textsuperscript{27,28} This results in cellular relaxation, and loosened cell–cell junctions and weakened focal contacts between cells and the surrounding matrix. Lat-B increases outflow facility in human\textsuperscript{19} and monkey (Gabelt, unpublished data 2011) organ-cultured anterior segments, and in live, nonhuman primates.\textsuperscript{14,15}

The mechanism of the Lat-B facility increase is thought to be due to changes in the structural geometry of the TM\textsuperscript{29} as a consequence of reduction in cell–cell and cell–matrix adhesion, along with impairment of cellular contractility. Treating the normotensive mon-
imately 8 AM (predose days 1 and 3) and 10 AM, and 12, 4, and 8 PM. Following the completion of each cohort (0.005%, 0.01%, and 0.02%) an unmasked analysis of all safety and tolerability assessments performed through day 7 (±2 days) was conducted and reviewed by a data monitoring committee (DMC) to determine if it was appropriate to continue to the next dose/cohort.

Subjects enrolled in this study were 18 to 75 years of age, had a diagnosis of bilateral ocular hypertension or early POAG, and had open healthy-appearing anterior chamber angles (grade 3 or 4). For the purposes of this study, early POAG was defined as focal nonfull thickness rim thinning with no visual field (VF) changes or small isolated nasal step or paracentral scotoma or Seidel's scotoma. The entry requirements for IOP were unmedicated IOP of 22 to 30 mm Hg at 8 AM (<4 mm Hg difference between eyes). Other entry requirements included best-corrected visual acuity (BCVA) in in both eyes of at least +0.5 LogMAR or better as assessed by Early Treatment Diabetic Retinopathy Study charts; corneal endothelial cell counts of at least 2000 cells/mm² (measured by noncontact specular microscopy) with normal morphology, and the ability and willingness to give signed informed consent and to follow study instructions.

Excluded from the study were individuals with closed angle, exfoliation syndrome, pigment dispersion, or secondary glaucoma; a history of glaucoma surgery (trabeculectomy, cryotherapy, etc.); cataract surgery within the past 3 months; progressive retinal or optic nerve disease apart from glaucoma, or history of chronic corticosteroid (topical or intraocular) use within the past month. Female subjects who were pregnant, lactating, or of childbearing potential and not using an acceptable method of birth control were excluded.

The screening examination included a physical exam, measurement of vital signs, complete blood count, chemistry panel and urinalysis assessment, visual acuity measurement (Early Treatment Diabetic Retinopathy Study charts), IOP, slit-lamp biomicroscopy, dilated ophthalmoscopy, corneal staining, automated visual fields (Humphrey program 24-2 SITA-standard strategy), ultrasonic pachymetry (contact), noncontact specular microscopy, anterior segment (nondilated) digital photos, the Roth 28 hue color vision test, and pupil measurement. Qualified individuals using topical ocular hypotensive under-went a washout as follows: prostaglandin analogues and β-adrenoceptor antagonists (6 weeks), α-adrenergic agonists and epinephrine-related medications (5 weeks), and pilocarpine or carbonic anhydrase inhibitors (7 days).

The key safety and efficacy endpoints were change in IOP, incidence of adverse events, change in endothelial cell count and morphology, change in corneal thickness, changes in slit-lamp, and fundus exam and change in visual acuity with and without manifest refraction.

Statistical methods: For all analyses, subject-level covariates were summarized within each cohort by subject classification (active-placebo versus placebo-placebo). Eye-level covariates were summarized by eye classification within subject classification. Categorical variables were generally summarized by the number and percentage of subjects in each category. Continuous variables were summarized using N, mean, SD, median, minimum, and maximum values. IOP for each day and time point, as well as diurnal values on days 1, 3, and 8, were summarized using Wilcoxon Signed-Rank test to assess treatment differences between eyes in subjects who received active treatment. Mean change values adjusted for baseline were generated using a mixed-effects model within cohort. The model included fixed effects for eyes (active eye, placebo eye from Active-Placebo subjects, and placebo eyes from Placebo-Placebo subjects) and baseline IOP with a random effect for subject. If the parameter between placebo eyes from Active-Placebo subjects and Placebo-Placebo subjects was nonsignificant, the adjusted means were presented for active-treated eyes versus placebo eyes.

All research followed the tenets of the Declaration of Helsinki and informed consent was obtained from the subjects after explanation of the nature and possible consequences of the study and where applicable, the research was approved by the institutional human experimentation committee or institutional review board (IRB).

Results

Patient Disposition and Demographics

A total of 56 individuals were enrolled as study patients. Of these, 40 were assigned to the intent-to-treat group, of which 38 patients completed the study (Table 1). One noncompleting patient was in the 2.5% protocol violation group and the other was in the 2.5% adverse event group.

The prestudy subject-level demographics and background characteristics (intent-to-treat population) are shown in Table 2.
Eye-level demographics and background characteristics (intent-to-treat population) are summarized in Table 3.

### Safety

A few and mild ocular adverse events, consisting mainly of redness and irritation indicate that INS115644 was generally well tolerated. The incidence of ocular adverse events in the safety population is summarized in Table 4. The safety population included all subjects receiving at least one dose of study medication (active or placebo) in the study. Transient changes in central corneal thickness were noted 4 hours post instillation. Increases were seen at the 0.005%, 0.02%, and 0.05% doses, while a decrease was seen at the 0.01% dose. The largest change was an increase of less than or equal to 2.5% at the 0.05% dose. Though there were statistically significant time points at each dose level, the changes in central corneal thickness were considered clinically insignificant. Table 5 summarizes the observed values and change from baseline measured by specular microscopy.

### IOP-Lowering Effect

Baseline IOPs were 22.9 ± 2.4 mm Hg and 23.5 ± 3.1 mm Hg in the 0.02% and 0.05% dose groups, respectively. Following the first instillation, 0.02% INS115644 reduced IOP (mean ± SD) by 3.8 ± 2.25 mm Hg (P = 0.002), and 0.05% INS115644 by 3.9 ± 3.1 mm Hg (P = 0.004) from baseline (17% reduction in IOP) at 4 hours post instillation. After the fifth instillation (day 3) IOP decreased from baseline by 5.4 ± 2.4 mm Hg (P = 0.004), a 24% reduction in IOP, in the 0.02% cohort and 2.8 ± 2.7 mm Hg (P = 0.02), a 12% reduction, in the 0.05% cohort at 4 hours post instillation (Fig. 1). INS115644 did not significantly lower IOP in the treated eyes compared with contralateral, placebo-control eyes at the two lowest doses.

Adjusting for diurnal baseline and IOP in the contralateral, placebo-treated eye, a maximal 12-hour hypotensive effect of 4.0 ± 0.5 mm Hg following the fifth instillation of 0.02% INS115644 was noted on day 3 (Fig. 2). A diurnal curve was assembled at baseline (IOPs were collected at 8 and 10 AM, 12, 4, and 8 PM). The two time points with the greatest IOP decrease compared with baseline were 4 hours post dose on days 1 and 3. At the 0.05% dose level a 3.9 mm Hg, or 17% decrease, was seen on day 1 and a 2.8 mm Hg, or 12% decrease, was seen on day 5. At the 0.02% dose level a 3.7 mm Hg, or 16% decrease, was seen at day 1 and a 5.4 mm Hg, or 24% decrease, was seen at day 5. Compared with the same baseline time-of-day IOP, a maximum decrease of 24% was noted at 4 hours post fifth instillation of 0.02% INS115644.

### Discussion

In this first-in-human 3-day, ascending dose Phase 1 study designed to evaluate the safety and tolerability of INS115644 (Lat-B) in patients with OHT or POAG, twice-daily INS115644 demonstrated ocular hypotensive efficacy in patients with elevated IOP. The two highest doses significantly lowered IOP at multiple time points compared with contralateral, placebo-control eyes. The greatest decreases, 17% to 24%, compared with the same baseline time-of-day, occurred 4 hours after instillation of the first and fifth doses at the two highest concentrations (0.05% and 0.02%).
Significant IOP reductions were sustained for 12 hours post instillation of the fifth dose at the 0.02% concentration, with a maximal 12-hour hypotensive effect of 4.0 ± 0.5 mm Hg, a 17% decrease, after adjusting for diurnal baseline and IOP in the contralateral, placebo-treated eye. The 0.02% concentration provided more significantly reduced IOP at more time points than the 0.05% concentration suggesting 0.02% as approximately the top of the dose response range.

While the reported IOP-lowering effects are not unusually large, further studies are needed to determine the scope of Lat-B’s potential clinical use, given the novel mechanism of action and potential to be additive to both secretory suppression and uveoscleral outflow enhancement drugs. The 12-hour maximal duration of action would indicate the need for twice daily dosing if used alone and perhaps even for adjunctive usage. Further studies to reduce the number of daily doses might include formulation improvements (to increase corneal penetration and bioavailability), sustained release options, modifying the molecule itself (Lat-B 2.0) or implantable delivery devices.

Few and mild ocular adverse events, consisting mainly of short-lived redness and irritation indicate that INS115644 was generally well tolerated. There were no systemic safety issues in the present study. The most common abnormality was conjunctival erythema/hyperemia, which occurred in both active- and placebo-treated eyes at most evaluations, including baseline. Only one patient was discontinued for an adverse event. This patient was treated with the 0.01% concentration and experienced several ocular events, namely, hyperemia, photophobia, keratitis, and eye irritation. The adverse event of ocular hyperemia has been reported previously in several clinical trials with Rho kinase inhibitors.\textsuperscript{21,22} It was suggested that the hyperemia could be the result of blood vessel relaxation, as ROCK inhibition induces smooth muscle relaxation.\textsuperscript{22} Hyperemia was not noted in the preclinical pharmacology monkey studies, perhaps

*Values represent the number of subjects experiencing a particular AE. A subject reporting more than one instance of a particular AE is only counted once.
because it is hard to see the vessels through the heavily-pigmented anterior conjunctiva and hard to see the more posterior but less pigmented conjunctiva. Monkey physiology data did indicate that Lat-B dose-dependently relaxes intraocular smooth muscles. Pupils dilated after phenylephrine administration dilated further relative to the contralateral controls 85 minutes after topical administration of 20 µL of 0.02% Lat-B. After pilocarpine was infused intramuscularly, the control pupils constricted but the pupils after 0.02% Lat-B did not. Although 0.02% Lat-B almost completely inhibited the miotic response to pilocarpine, it inhibited the accommodative response to pilocarpine by only up to 25%. This discrepancy

Mean (SD), n = 10.

Figure 1. Effects of INS115644 on IOP in subjects with OHT and POAG. Following the fifth instillation (day 3) IOP decreased from baseline by 5.4 ± 2.4 mm Hg (P = 0.004) and 2.8 ± 2.7 mm Hg (P = 0.02) in the 0.02% and 0.05% cohorts, respectively, at 4 hours post instillation. Wilcoxon Signed-Rank test comparing IOP of active eye to placebo eye in Active-Placebo subjects.
might be a pharmacodynamic issue; drug levels reaching the CM might be less than those reaching the iris sphincter muscle.

A transient, clinically insignificant increase in central corneal thickness of less than or equal to 2.5% was noted 4 hours post instillation, while corneal endothelial cell density remained unchanged. In monkeys, a single dose of 20 μL of 500 μM (~0.02%) Lat-B administered topically, produced a transient increase in corneal thickness of approximately 10% at 3.5 hours post dose and 6% at hour 6. Midperipheral corneal thickness also increased 2 to 5 hours after Lat-B administration in monkeys, with the greatest increase, 6%, at 3 hours. In separate studies, corneal thickness was not changed after 1 or 9 dose(s) of 0.01% Lat-B. Reversible abnormal corneal endothelial cell morphology, from specular microscopy observations, was noted in the higher dose groups. In monkey studies, by electron microscopy, the morphology of the corneal endothelium was unchanged (all junctional elements, including tight junctions, adherens junctions, and gap junctions were retained) after intracameral exchange and perfusion with 0.5 μM Lat-B, a concentration that affected the TM and increased outflow facility.

Combination drug effects tested during in vivo monkey experiments in which H-7 was administered by AC exchange and cytochalasin B (CB) doses were given by bolus AC injection demonstrated that combining subthreshold doses of CB and a maximal dose of H-7 produced facility increases significantly higher than those produced by H-7 alone, and combining a near-maximal dose of CB and a maximal dose of H-7 produced a facility increase of greater magnitude than either alone. These findings could indicate that the pathways by which H-7 and CB increase outflow facility converge at some point, resulting in deterioration of actin microfilaments in the TM and alterations of cell–cell and/or cell–extracellular matrix adhesions. Alternatively, the findings could indicate that H-7 and CB may increase facility at least in part by different mechanisms with CB-induced cellular contractions disrupting cell–cell adhesion, complimenting H-7’s predominant effects on cell–extracellular matrix adhesion. Additive IOP lowering effects of Lat-B combined with Rho-kinase inhibitors would need to be studied directly with these specific compounds, but it is possible that the mechanisms of action would be complementary and the combination would enhance IOP lowering effects.
Altering the actin microfilament system (by cytochalasins, latrunculins, etc.) or actomyosin contractility (by myosin light-chain kinase or Rho-kinase inhibitors; by over-expression of caldesmon, which in essence uncouples actin from myosin; or C3, which affects actin-myosin interactions by inhibiting Rho-GTP (guanosine triphosphate) at the beginning of the Rho activation cascade) reduces outflow resistance in nonhuman primates in vivo and/or in vitro. Morphological studies done with Lat-B and other cytoskeletal agents show that there are key common effects: relaxation of the TM and expansion of the JCT, and relaxation and flattening and spreading out of the SC inner wall endothelial cells, and consequent dilation of the canal.10,15

The clean slit-lamp exams in our patients, the reversibility of the TM effect, the absence of anterior segment adverse events and the healthy retina studies in monkeys, all bode well for Lat-B’s safety clinical use. Our findings demonstrate that INS115644 may be a safe topical agent that is effective in reducing IOP in OHT and POAG patients. The magnitude of the IOP-lowering effect of INS115644 Ophthalmic Solution observed in this study warrants further investigation in larger clinical trials. With its unique mechanism of action, this drug has the potential to positively add to current pharmacological interventions.
